Element I

Keywords: GPS continuous, GPS campaign, regional seismic hazard

### **NON-TECHNICAL SUMMARY**

Data to assess active faulting in Puerto Rico and the Virgin Islands were obtained using Global Positioning System (GPS) geodesy. Analysis of the GPS data is consistent with EW-oriented extension across the island of Puerto Rico. Extension is greater in the west than east. The loci of deformation are not known, but preliminary results indicate that the active structures are likely west of the San Juan metropolitan area. EW-extension that may be accommodated along subaerial faults in Puerto Rico has not previously been recognized and thus not considered in seismic hazard analysis of the island.

### **SUMMARY**

This annual report is submitted in keeping with the requirements as described in the award. The start date of this 2-year project was March 1, 2004.

Data to assess active faulting and diffuse extension in Puerto Rico and the Virgin Islands (PRVI) were obtained using Global Positioning System (GPS) geodesy, building on earlier work conducted in PRVI and also funded by NEHRP. Analysis of the GPS data is consistent with westward-increasing EW-extension across PRVI, including EW-extension of a few mm/yr across the island of Puerto Rico. The loci of deformation are not known, but preliminary results indicate that the structures are likely west of the San Juan metropolitan area. EW-extension that may be accommodated along subaerial faults in Puerto Rico has not previously been considered in seismic hazard analysis of the island.

### **INVESTIGATIONS UNDERTAKEN**

**Overview and background:** Hundreds of earthquakes per year occur within and around Puerto Rico and the Virgin Islands (Figure 1a). The majority of events are small and located offshore. Several large events have occurred in historic time, including the 1916, 1918, and 1943 Mona Passage earthquakes ( $M_s=7.2$ , 7.3, and 7.5 respectively), the 1867 Anegada earthquake ( $M_s=7.3$ ), the 1787 Puerto Rico trench earthquake ( $M=7.5?$ ) and the 1670 San German earthquake ( $M=6.5?$ ) (Pacheco and Sykes, 1992). Noting the concentration of both current seismicity and historic events offshore (Figure 1c), several workers proposed a rigid Puerto Rico-northern Virgin Islands block (PRVI) in the northeastern corner of the Caribbean (Byrne et al., 1985; Masson and Scanlon, 1991). The result of our earlier GPS geodetic project funded by USGS-NEHRP does support the existence of a distinct PRVI microplate that translates  $2.6\pm 2.0$  mm/yr toward  $N82.5^\circ W \pm 34^\circ$  (95%). The GPS data also suggest that westward-increasing EW-

extension occurs across Puerto Rico and the northern Virgin Islands from zero in the east at Virgin Gorda to  $5\pm 2$  mm/yr across the Mona Canyon between Hispaniola and western Puerto Rico. EW-extension of  $3\pm 1$  mm/yr may be accommodated across the island of Puerto Rico. The loci of deformation are not known. Preliminary results indicate that the structures may be west of the San Juan metropolitan area, but additional time on existing sites is necessary to define this and other remaining uncertainties better. EW-extension across PRVI that may be accommodated along subaerial faults in Puerto Rico has not previously been considered in seismic hazard analysis of the island. Past attention has been centered on the Lajas Valley in the southwestern part of the island where seismicity levels are the highest in PRVI (Figure 2).

Most studies of on-land faults in Puerto Rico have focused primarily on structures that cut Tertiary and older rocks (Glover, 1971; Erickson et al., 1990). Prior to the work of Prentice et al. (2005), documentation of features that offset Quaternary units has been limited (e.g. McCann, 1985; Meltzer et al., 1995), leaving most workers to model Puerto Rico as a rigid block (e.g. Masson and Scanlon, 1991). Shallow microseismicity does occur onshore, but the historic record is consistent with major events limited to the offshore region (McCann, 2002). The recognition of Quaternary displacements when coupled with observations of shallow seismicity in western Puerto Rico, however, appears to argue against truly rigid-block behavior. The questions to be answered as part of this project are:

- *What are the permissible displacement rates along the mapped faults given the GPS geodetic results?*
- *Do these rates agree with those derived from the geologic data?*
- *Are these rates consistent with significant and, therefore, possibly destructive earthquakes occurring along subaerial faults within PRVI?*

Because the GPS-derived residual velocities of individual sites in PRVI are small (on the order of a few mm/yr) and the Caribbean reference frame is poorly constrained, errors remain large and limit estimation of discrete fault slip rates. In addition, many of the PRVI sites have short (< 4 year) time series. One of the goals of this project is to reduce the errors significantly by the additional two-years of data to be collected during the tenure of this award. Furthermore, all existing and newly acquired GPS data have now been reprocessed using the latest release of GIPSY-OASISII (v. 2.6.4) and an updated Caribbean reference frame. We also included analysis modules that allow for estimation of tropospheric gradients and rigorous calculation of ocean loading effects and incorporate qualitative estimates of correlated site motion for all sites in the northeastern Caribbean.

While our previous research has unequivocally established that individual site velocities derived from our preliminary GPS dataset have measurable and statistically significant residuals relative to the Caribbean plate (Jansma et al., 2000), the mechanism responsible has not yet been established. The current surface deformation field may be treated as a manifestation of 1) a kinematically distinct microplate between the North American and Caribbean plates; 2) a reflection of elastic strain accumulation along major offshore faults or the subduction interface; or 3) a viscoelastic response to large historical earthquakes. Determining which of these possibilities accounts for the residual velocities is an essential constraint to seismic hazard and risk analysis for the region. For

example, in the case of elastic strain accumulation along the plate interface, the potential of large, devastating earthquakes, for which Puerto Rico is not adequately prepared, is significant. The probability of frequent, large events is less likely for a freely translating microplate. Quantitative modeling of the results, therefore, is a key objective of this proposal.

### **GPS network in PRVI**

GPS measurements were first collected in the northeastern Caribbean in 1986 at six locations (Figure 1b) and were re-occupied as part of CANAPE (CARibbean-North American Plate Experiment) in 1994. The network was densified during CANAPE and each subsequent year (Dixon et al., 1998; Jansma et al., 2000; Calais et al., 2002). Since 1994, measurements have been made on subsets of the entire network each year.

The GPS network in Puerto Rico and the Virgin Islands (Figure 2) consists of the original 1994 CANAPE locations (ISAB, PARG, and GORD) plus campaign sites MIRA (Miradero-Mayagüez), ZSUA and ZSUB (San Juan), MAZC (Mayagüez airport), CIDE (UPRM), MONA (Mona island), DSCH (Desecheo island), ADJU (Adjuntas), ARC1 and ARC2 (Arecibo), CCM5 (Ponce), VEGA (Vega Alta), CAJA, (Caja de Muertos Island), FAJA (Fajardo), LAJ1, LAJ2, and LAJ3 (Lajas Valley), SALN (Salinas), VIEQ (Vieques), and ANEG (Anegada, British Virgin Islands) and continuous sites GEOL in Mayagüez, FAJA in Fajardo, UPRR in Rio Piedras, and UPRH in Humacao operated by the Department of Geosciences, University of Arkansas, and PUR3 in Aguadilla maintained by the U.S. Coast Guard. FAJA, UPRR and UPRH were established in 2000 as part of an earlier NEHRP award. We have added two campaign sites in the British Virgin Islands, BEEF and BREW in eastern and western Tortola, respectively, for which two-epoch velocities are now available. ANEG, VIEQ, MONA and DSCH also now have two-epoch velocities.

All of the sites in Puerto Rico and its islands (Mona, Desecheo, Vieques, Caja de Muertos) were re-occupied during 2005 as part of this project. Occupations consist of a minimum of 8 hours of data collection each day for 3 days. Sites in Puerto Rico were re-occupied by Mr. Andy Eaby who serves under contract to us as part of this project. Sites in the British Virgin Islands were re-occupied by graduate student Henry Turner of the University of Arkansas and NSF-REU (Research Experiences for Undergraduates) students Sarah Stamps of the University of Memphis and Adrian Baldwin of the University of Arkansas, Pine Bluff. One problem that we have diagnosed is a faulty receiver/antenna combination that has given us erroneous measurements. For this reason, the results presented here are extremely preliminary for the newest velocities. We are in the process of correcting for the error and re-processing the data. Additional occupations are vital to ensure confidence in the results.

### **GPS data processing**

Processing of GPS data is done with GIPSY-OASIS on a Dell Precision 650 running RH Linux (WS 3.3). station-day to <11 s per station-day for a 24 hr absolute point position estimate. We include ocean loading in our Earth models within GOA-II on the calculated point positions. Ocean loading coefficients for every UARK observation site and all IGS sites analyzed by our lab have been obtained using the model of olfg/olmpp by Scherneck. In addition, we have calculated common mode corrections for all our observations. As mentioned above, we currently are correcting for the fault receiver-antenna combination. We anticipate this analysis to be completed in the next few months.

### **Quantitative modeling**

We have developed kinematic-coupling models to examine elastic strain accumulation and co-seismic displacements in obliquely convergent margins such as the northeastern Caribbean. Our initial efforts use simple 2D elastic models based in the formulation of Savage (1982). While these simple models allow one to explore the control of slab dip angle, degree of kinematic coupling, and locking depth, they are not adequate to address the complex geometry and kinematics of the PRVI subduction zone and Lesser Antilles arc. We have now developed 3D elastic dislocation models for the geometry and plate kinematics of the PRVI, Lesser Antilles, and Middle America subduction zones. This was done using the Department of Energy code DISL (Larsen, 1998), which is based on the formulations of Chinnery (1961), Savage and Hastie (1966), and Mansinha et al. (1971). This code allows one to include a more realistic geometry of a curved subduction interface, by calculating the displacement on a series of linked fault patches. It retains the constraint of determining the displacements for an elastic half-space, however. We also have the license for GeoFEST, which is a 3D finite element code developed by NASA at JPL to investigate a wide variety of geophysical phenomena. GeoFEST allows us to investigate the effects of visco-elastic and other crustal/mantle rheologies as well as slab texture on the observed surface displacement field. GeoFEST is designed to run in a parallel computing environment, and its successful operation depends on a number of subsidiary software modules.

### **Results**

The current GPS-derived velocity field is shown in Figure 3. Our reprocessing experiments, which include the effect of ocean loading at a limited number of CGPS sites (including PUR3, GEOL, FAJA, and HUMA), demonstrate that there is significant improvement in the precision of the site positions, lowering our noise estimates on the calculated velocities. The effect is most pronounced in the east and vertical components, with an improvement of 4.3% and 21.6%, respectively. Common mode corrections, which are weighted by the inverse square of radial distance from our regional and other far-field CGPS sites, also lowers noise estimates substantially on the campaign sites. Velocities at BEEF, BREW and VIEQ, for which only two epochs are available, are significantly different from those elsewhere in the northern Virgin Islands and eastern Puerto Rico. The possibility exists that the faulty antenna/receiver combination were used at these sites. We currently are determining if this was the case. The velocity at ANEG seems more reasonable, but is faster than that expected given the velocity at

GORD. Additional data collection is necessary as is further data processing to correct for the bias that the faulty antenna/receiver pair introduces.

## **ABSTRACTS**

Stamps, S., G. Mattioli, P. Jansma, H. Turner and A. Baldwin, 2005, Assessing the rigidity of the Puerto Rico-Virgin Islands microplate: results from GPS geodesy in the British Virgin Islands, American Geophysical Union Annual Meeting, San Francisco, California, December 2005.

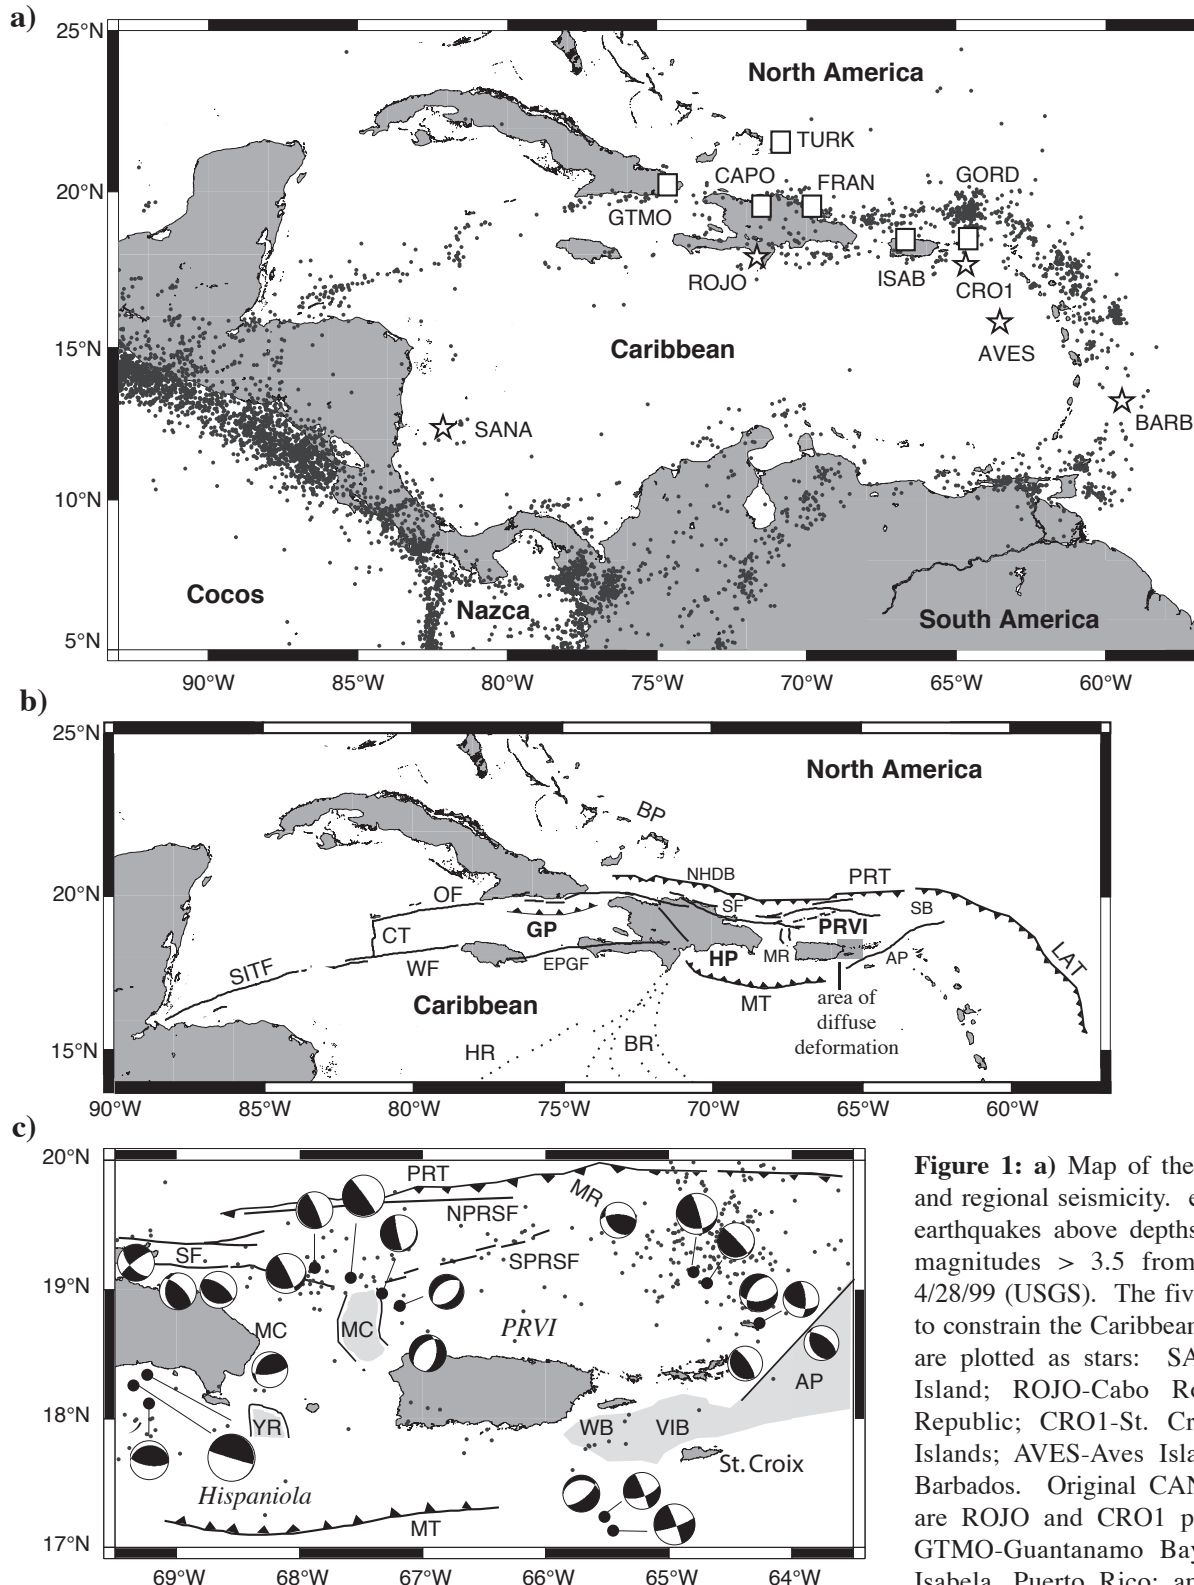

## **DATA AVAILABILITY**

The campaign and continuous GPS data are being archived locally and backed up to DAT and CD. UPRM/UA raw data are not yet publicly available by ftp, because security issues regarding full public access have not been worked out and dedicated computational resources for such public access are not available at this time. Currently, all UPRM/UA GPS data through 2003 have been placed in the UNAVCO archive following the standard procedures established by the GPS community. PUR3 and CRO1 data are available on-line through the standard archives.
